Unreleased

ABSTRACT

We report analysis of an 8 hr observation of PSR B0943+10 at 325 MHz performed at the Giant Metrewave Radio Telescope (GMRT) in India. B0943+10 is well known for displaying regular sub-pulse drifting and two emission modes. We investigate the modal behavior of B0943+10. As a rough estimate, we find the pulsar spends about 7.5 hrs in the 'B' mode and about 2.2 hrs in the 'Q' mode, on average. Although the pulsar can switch modes within one pulse, the sub-pulse drift rate changes with a characteristic time of 1.2 hrs over the course of a 'B' mode. Under the subbeam carousel model we find the drift-rate changes are produced by a 10% increase in the average number of subbeams and a 16% increase in the carousel circulation time. We speculate that under the partially screened gap model the increase in circulation time should be related to a small increase in the neutron star surface temperature.

Key words: MHD — plasmas — pulsars: general, individual (B0943+10) — radiation mechanism: nonthermal — polarisation — mode-changing phenomenon

I. INTRODUCTION

Pulsar B0943+10 is well known as a paradigm example of moding and subpulse drifting in pulsars. In the 'B'urst mode, the pulsar displays strong, regular subpulse drifting, while in the 'Q'uiescent mode the drifting disappears and only hints of a modulation feature have been found [Rankin & Suleymanova (2006)]. During the 'Q' mode, B0943+10 grows dimmer and a precursor component (hereafter: PC) appears whose peak precedes the peak of the main pulse (hereafter: MP) by some 50°, as discovered in Backus et al.

The papers in this series¹ have investigated at length the dynamic behaviors of B0943+10. A regular modulation feature appearing at $\sim 0.47 P_1$ (hereafter: $f_{3.obs}$) was found. In Paper I it was argued that this was a first order alias of the true modulation frequency lying at $\sim 0.53 P_1$ (hereafter: f_3). Paper IV argued that there are gradual changes in f_3 over the course of a 'B'-mode interval with the remarkably long time scale of 1.2 hrs.

This series has investigated whether B0943+10's highly regular drift modulation might be understood on the basis of the subbeam carousel model (hereafter: CM). It was demonstrated that the subpulse pattern of B0943+10 is produced by a carousel of 20 subbeams rotating with a circulation time \hat{P}_3 of some 37 P_1 . The projection of the carousel on a plane perpendicular to the magnetic axis is treated as quite circular.

Physically, the carousel is thought to be produced by 'spark'-induced columns of relativistic primary plasma directed into the open polar flux tube. Under $\mathbf{E} \times \mathbf{B}$ drift the plasma columns precess around the magnetic axis. This model was introduced by Ruderman & Sutherland (1975) and has been further developed since [see Gil & Sendyk (2000)].

In this paper we present a nearly 8-hr long observation of B0943+10 carried out using the Giant Metrewave Radio Telescope (GMRT) in India. This long observation has allowed us to confirm the slow changes of the pulsar's behavior in its 'B' mode as discussed in Papers IV & V.

§II provides a detailed description of the long GMRT observation as well as of the older Arecibo Observatory (AO) observations used below. In §III we investigate the modal evolution of B0943+10 and confirm the gradual variation of

The papers in the *Topology and Polarization* series are: Deshpande & Rankin (2001) [hereafter: Paper I]; Asgekar & Deshpande (2001) [Paper II]; Rankin et al. (2003) [Paper III]; Rankin & Suleymanova (2006) [Paper IV]; and Suleymanova & Rankin (2009) [Paper V].

 f_3 during the 'B' mode with a time scale of 1.2 hrs. This result allows confirmation of the slow 'B'-mode profile-shape changes with the same time scale ($Paper\ IV\ \&\ V$). Overall we found that the 'B'- and 'Q'-mode intervals had typical durations of some 7.5 and 2.2 hrs, respectively. §IV investigates the observed change in the primary modulation frequency f_3 . We resolve a decrease in the subpulse spacing (P_2) of about 10% over the course of a 'B' mode. We find that the carousel angular velocity (hereafter: $\omega_c\ [= 2\pi/\hat{P}_3]$) decreases by nearly 20%, corresponding to a nearly 20% increase in \hat{P}_3 . Finally §V provides a discussion of these results.

II. OBSERVATIONS

1. Observing setup

The 325-MHz pulse sequences (hereafter: PS) were acquired using the Giant Meterwave Radio Telescope (GMRT) near Pune, India. The GMRT is a multi-element aperturesynthesis telescope (Swarup et al. 1991) consisting of 30 antennas distributed over a 25-km diameter area which can be configured as a single dish in both coherent and incoherent array modes of operation. The observations discussed here used the coherent (or more commonly called "phased array") mode (Gupta et al. 2000; Sirothia 2000) in the upper of the two 16-MHz sidebands. At either frequency rightand left-hand circularly polarized complex voltages arrive at the sampler from each antenna. The voltage signals were subsequently sampled at the Nyquist rate and processed through a digital receiver system consisting of a correlator, the GMRT array combiner (GAC), and a pulsar back-end. In the GAC the signals selected by the user are added in phase and fed to the pulsar backend. The pulsar back-end computes the power levels, which were then recorded at a sampling interval of 0.512 msec.

2. Data reduction, interference mitigation

In order to put the GMRT observation of B0943+10 into serviceable shape, there were several interference and observational artifacts which had to be addressed. Due to instrumental effects, the baseline varied on timescales of 10 s or more. To cope with this, a running mean subtraction was performed. The on-pulse regions were gated and replaced by random samples from nearby off-pulse regions. 2 s and then 5 s running means were performed accordingly and subtracted from the time series.

Electrical interference at 50 Hz was strong. To mitigate this, after performing the running mean subtraction, an FFT of about 1 million samples was performed on the dedispersed time series, beginning at the first sample. In the frequency domain, the real and imaginary components corresponding to the regions around the fundamental frequency and its harmonics were replaced by randomly selected nearby samples. An inverse FFT was performed and the same process was repeated on the remaining samples in the time series. This process could not remove all the 50-Hz interference, due to its unstable frequency and spectral leakage. To account for spectral leakage, large regions around the fundamental frequency and its harmonics would have needed to be re-

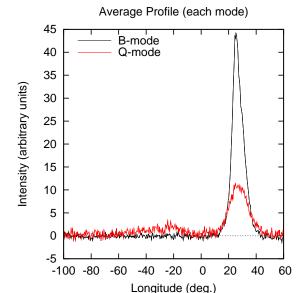

Figure 1. Average intensity profiles for both modes. The 'B' mode (in black) is much brighter than the 'Q' mode (in red). The 'B' mode profile is taken from several thousand pulses in the first 'B' mode apparition (B1). There is a $\sim 5\sigma$ detection of the PC lying $\sim 50^{\circ}$ before the MP during the 'Q' mode, agreeing with Backus et al. (2010). While the MP is dimmer during the 'Q' mode, it is significantly wider.

moved, but this would have interfered with the pulsar signal and distorted the time series.

Finally, an apparent gradual shift in the phase of the pulsar of about 10° during the 8-hr observation was present in the data. 2500-pulse averages were performed and the center of the MP profile was determined for each section of the data. The period used to bin the data into individual pulses was adjusted over the course of the observation to account for the small changes in phase of the profile.

3. Overview of reduced observation

The most important aspect of this observation is its sheer length. The observation spans almost 8 hr, with 23,160 pulses available (after truncation due to running mean subtraction). There were four breaks in the observation. After 30-min the telescope was stopped for about 13 min in order to recheck the phasing. Over the following 7 hr there were three ~ 10 min breaks in the observation spaced more or less evenly during which time the telescope was pointed to a bright nearby source to rephase the antennae. Figure 2 shows the pulse sequence for this long observation as a stack of 100-pulse averages. Figure 2(a) shows the 30 min of observation before the long 13-min break. Figure 2(b) shows the remaining ~ 7 hr following the break.

The length of the modes in B0943+10 is on the order of 2 or more hours, so it is highly unlikely that an entire mode would be missed due to such breaks, although the boundary between two modes could occur during an observational break. Luckily, as can be seen in figure 2(b), the two observed mode changes did not occur during breaks, allowing a good estimation of the position of the modal boundary.

Because of the importance of the long 7-hr stretch after the initial 13-min break, we will follow the convention of setting pulse 0 to the beginning of this stretch. The modal sequence in this observation is as follows: 'B' mode from pulses -2409 to 10270; 'Q' mode from pulses 10270 to 15250; then back to 'B' mode from pulses 15250 to 23209. The observational breaks fall at the following pulse intervals: -788 to 0; 3,375 to 4,250; 10,705 to 11,100; 17,775 to 18,175.

B0943+10 is not very bright at 325 MHz, and so the increased sensitivity available at AO made the observations reported in $Papers\ I\ \mathcal{E}\ IV$ significantly higher quality than the long observation presented here. This prevents certain analyses performed in previous papers, but the great length of this observation opens a new path for inquiry.

We confirm the presence of a precursor (PC) lying 52° before the main pulse (MP) observable in the total intensity only during the 'Q' mode (see Fig. 1). After averaging several thousand 'Q' mode pulses, the PC is visible at a peak level of about 5 times the off-pulse rms. As with all previous observations, the MP is brighter in the 'B' mode, and dimmer but wider in the 'Q' mode.

III. GRADUAL MODAL EVOLUTION

Paper IV announced the discovery of behaviors associated with the evolution of the modes in B0943+10. At 'B' mode onset, gradual changes in the relative amplitudes of the leading (A1) and trailing (A2) components of the MP were detected, with the ratio of the amplitudes A(2/1) decaying exponentially from 1.75 to about 0.2 (at 327 MHz). The carousel circulation time (hereafter: \hat{P}_3) at 'B'-mode onset was found to increase from 37.3 P_1 to around 37.8 P_1 as an exponential of the form $[1 - exp(-t/\tau)]$, where τ is the characteristic time. For both the change in A(2/1) and \hat{P}_3 , the characteristic time was found to be some 73 minutes, or 1.2 hours. (see Figs 5 and 8, Paper IV) Paper V found that the fractional linear polarization of the MP increases from 3 to 50% over the course of a 'B' mode.

However, a full justification for these results remained elusive. Such dynamics can have important implications for understanding the origins of modes in pulsars, as long as it can be shown that these changes occur consistently and can therefore be linked with the evolution of a mode. Paper IV only had access to observations about 2 hours long at the longest, which introduced several obstacles: an entire mode was never observed from start to finish; only one 'B' to 'Q' mode transition had been seen (and that observation was only 986 pulses long); and the longest the pulsar had been observed from 'B' mode onset onward was some 3900 pulses (1.2 hr). Paper V only had access to short observations 4 to 15 min in length and determined the dependence of the fractional linear polarization as a function of time after 'B' mode onset from the apparent time dependence of \hat{P}_3 established in Paper IV.

The decrease of the amplitude ratio A(2/1) and the increase of \hat{P}_3 throughout the 'B' mode both depended on an imprecise argument involving the splicing together of data from several observations by noting the apparent exponential nature of these changes at 'B' mode onset.

We confirm the evolution of the frequency modulation during the course of 'B' mode as determined in *Paper IV*. To make the timescale of the changes determined in this paper independent of aliasing and model, we examine the frequency of the observed primary modulation feature $(f_{3,obs})$, rather than \hat{P}_3 as in $Paper\ I-V$. Under the carousel model, $\hat{P}_3 = N/f_{3,true}$ where N is the number of subbeams and $f_{3,true}$ is the un-aliased frequency of the primary modulation feature. $Paper\ I$ and Backus et al. (2010) argued that the observed modulation is a first order alias of the true feature such that $f_{3,true} = 1 - f_{3,obs}$, and that N = 20. Accordingly, $\hat{P}_3 = 20/(1 - f_{3,obs})$, so the timescales of the small changes in \hat{P}_3 will be reflected in the timescales observed in $f_{3,obs}$ given the gradual exponential behavior of the changes.

Figure 3(a) shows a plot of $f_{3,obs}$ vs pulse number for the long January, 2010 GMRT observation. $f_{3,obs}$ was determined by performing 512 point LRF's every 50 pulses. LRF's with a poorly defined primary modulation feature were discarded. Each LRF overlaps the next by 462 pulses, so adjacent points are largely redundant, but allow the stability of the feature to be determined.

We confirm the characteristic time of $\tau = 73$ min (1.2 hr) for the increasing $f_{3,obs}$. Fitting an exponential function to the circulation time as function of pulse number (see Fig. 3) for the second 'B'-mode apparition, we find

$$f_{3,obs}(t) \approx 0.471 - 0.022e^{-t/\tau}$$
 (1)

where t=0 at 'B'-mode onset. Significantly, B0943+10 was observed for 7960 pulses after 'B'-mode onset, more than twice as long as in any previous observation, and the exponential behavior continues for the entire time.

With the \sim 4 hours of observation before 'Q'-mode onset we see very clearly that at the end of a 'B' mode, $f_{3,obs}$ has increased to about 5% higher than at 'B' mode onset. $f_{3,obs}$ is largely constant during the first 'B' mode apparation which is to be expected at the end of 'B' mode if $f_{3,obs}$ follows the form of eq.(1). It is also observed that $f_{3,obs}$ has decreased 5% following the 'Q' mode, implying that the relation in eq.(1) is indeed a regular feature of the 'B' mode and is not an illusion due to observations spaced over the course of days or years.

We are now prepared to sketch out the long-term evolution of the modes. From this long observation it is clear that $f_{3,obs}$ changes exponentially as a function of the form of eq.(1) during a single 'B' mode. If we consider this change to be continuous, then we may reconstruct an entire 'B' mode from the data within this long GMRT observation. Fig. 3(a) shows $f_{3,obs}$ as a function of time as observed. Fig. 3(b) shows $f_{3,obs}$ as a function of time for such a reconstruction.

To reconstruct a 'B' mode from start to finish as in Fig. 3(b), the beginning of the second 'B' mode apparition (B2) was set to t=0. $f_{3,obs}$ at the beginning of the first 'B' mode apparition (B1) is greater than at the end of B2, indicating that B1 comes later in the modal evolution than does B2. Thus, the first 'B' mode (B1) was shifted in time to come after B2.

To determine a reasonable spacing between the end of B2 and the beginning of B1 in the reconstructed sequence, an exponential function of the form of eq.(1) was fitted to the $f_{3,obs}$ in both regions for spacings between 0 and 55,000 pulses (enough to be essentially infinite). The fit is mostly constrained by the more steeply varying values in B2, so the constants in eq.(1) are not affected significantly by the spacing (Δ) . The rms of the residuals was found to decay

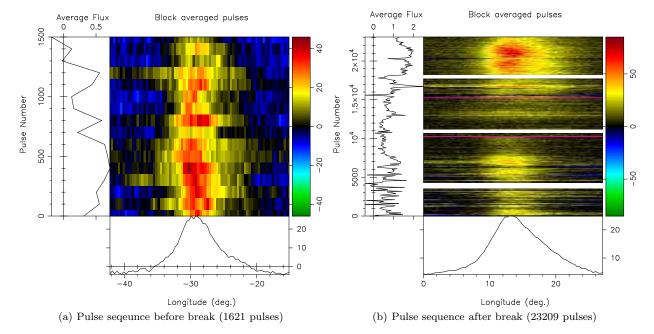

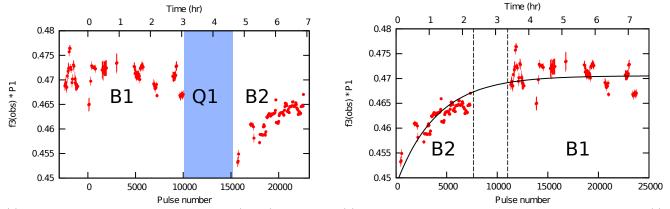

Figure 2. Pulse sequences for the January, 2010 GMRT observation at 325 MHz. (a) shows the first 1621 pulses of the observation, (b) shows the remaining 23209 pulses which were observed following a 13-minute break in the observation. The horizontal magenta lines in the center panel of (b) mark the beginning and end of the 'Q' mode. The white lines mark the three occasions where the telescope went off-source to rephase the antennae. The center panel shows a stack of 100-pulse averages, with time increasing along the +y-axis. The left panels show the integrated flux for each 100-pulse average and the bottom panel shows the profile averaged over all pulses in the window. 27° around the MP are displayed. The intensity scale and the 0° longitude are arbitrary.

(a) Observed primary modulation frequency $(f_{3,obs})$ for the 2010 GMRT observation of B0943+10. The pulsar is in the 'Q' mode approximately from pulse 10270 to pulse 15250—indicated by the vertical blue stripe and labeled Q1—where no regular modulation is detected. In the first 'B'-mode apparition (B1), $f_{3,obs}$ fluctuates around 0.47 cycles/ P_1 . At the onset of the second 'B' mode (B2), $f_{3,obs}$ increases from \sim 0.45 cycles/ P_1 to \sim 0.47 cycles/ P_1 . Using an exponential fit (eq.1), the characteristic time of this increase is 73 min, or 1.2 hr. 512-point LRF's were performed every 50 pulses. LRF's where the modulation was poorly defined were discarded. The larger error bars in the first 'B' mode may be attributed to poorer observational quality.

(b) $f_{3,obs}$ for the 2010 GMRT observation of B0943+10 as in (a), but with the sections rearranged. Pulse 0 is set to the beginning of region B2, corresponding to pulse 15250 in (a), and the region B1 is placed to begin at about pulse 11,000. An exponential was fitted to the data (see eq.1) and is plotted as a solid black line. The 7.5 hrs from 'B' mode onset at the beginning of B2 until 'Q' mode onset at the end of B1 represents a good lower limit on the length of 'B' modes.

Figure 3. Observed primary modulation feature $(f_{3,obs})$ as a function of time for the Jan 2010 GMRT observation. (a) The entire 8-hr observation. (b) Entire reconstructed 'B' mode from the data in (a).

exponentially as $rms = a + be^{-\Delta/\Delta_c}$ where the characteristic spacing $\Delta_c = 3250$ pulses. Thus, the quality of the fit remains nearly constant for $\Delta \ge 4000$ pulses.

This sets a lower limit on the length of the 'B' mode. We find the 'B' mode should be at least 24,600 pulses (7.5 hr). We can review the plausibility of this as a lower limit, as well as a rough estimate of the actual 'B' mode length by considering the fraction of time B0943+10 is observed to be in each mode. We have 31.2 hrs of observations available composed of 24.0 hr in 'B' mode and 7.2 hr in 'Q' mode. The pulsar is therefore observed to be in the 'B' mode 77% of the time and in the 'Q' mode the remaining 23%.

If the average 'B' mode length is 7.5 hrs, then we can expect the average 'Q'-mode length to be 2.2 hrs, which seems to agree with observation. In the GMRT observation, the 'Q' mode is 1.5 hrs long; whereas in the only other complete 'Q' mode known (Rankin & Stappers 2008), the duration is almost exactly 1 hr. In no other observation is an entire 'Q' mode seen, but there are two other instances where more than 1.5 hrs of continuous 'Q' mode is observed. That no other complete 'Q' modes are observed is unsurprising if 'Q' modes average 2.2 hr, given the $\sim\!\!2.5$ hr that B0943+10 is visible to AO.

It should be stressed that these timescales are estimates and are not expected to be exact, yet they do provide insight. Significant deviation from these values for a given mode should be expected.

We may now re-address the findings of Papers IV & V. We confirm that the exponential changes in $f_{3,obs}$ as a function of time persist throughout the 'B' mode, thus allowing the estimation of the location of given observation in the 'B' mode evolution by measuring its $f_{3,obs}$ (or \hat{P}_3 as in Paper IV and V). Determining the exponential decay in the ratio of the trailing and leading components of the profile [A(2/1)] was dependent on knowing that $f_{3,obs}$ indeed evolves exponentially with the same timescale found in this paper. Finally, the increase in fractional linear polarization as a function of location in 'B' mode depended on estimating the position of short observations in 'B' mode from $f_{3,obs}$.

We can therefore describe the evolution of the modes in B0943+10. At 'B' mode onset, the average profile shape changes abruptly, a precursor component virtually disappears [Backus et al. (2010)], and a strong primary modulation feature becomes visible in LRF's. Over the span of some 7.5 hr the frequency of the feature changes as an exponential function of the form of eq.(1) by some 5%. The profile shape changes exponentially with the same time scale as $f_{3,obs}$ (Paper IV). The fractional linear polarization increases throughout the 'B' mode ($Paper\ V$). At 'B'-mode cessation the profile switches abruptly and the strong modulation feature disappears. The PC brightens to detectable levels and the pulsar then spends around 2.2 hr in the 'Q' mode. Remarkably this behavior is a confirmation of the assorted observations reported in Backus et al. (2010) and Papers I-V.

IV. CHANGE IN MODULATION UNDER CAROUSEL MODEL

We proceed to interpret the evolution of the primary modulation under the CM. The analysis presented in $Paper\ I$ and

Backus et al. (2010) showed that the 'B' mode of B0943+10 displays a rotating-subbeam carousel comprised. For three PS's of several hundred pulses, spanning the entire 'B'-mode, the number of subbeams was measured to be 20. $f_{3,obs}$ is argued to be a first order alias of the true primary modulation frequency $f_{3,true}$ such that $f_{3,true} = 1 - f_{3,obs}$. We can therefore find the true P_3 and the carousel circulation time (\hat{P}_3 here, often referred to as P_4):

$$P_3 = \frac{1}{1 - f_{3,obs}} \tag{2}$$

$$\hat{P}_3 = 20P_3 = \frac{20}{1 - f_{3,obs}} \tag{3}$$

In this case, P_3 and \hat{P}_3 will evolve similarly to $f_{3,obs}$: they will increase as an exponential function of the form of eq.(1), changing by about 5% over the 'B' mode. Any fractional changes in P_3 will be reflected in similar changes in $f_{3,obs}$.

We may now investigate what changes in the carousel could account for the $\sim 5\%$ change in P_3 . For B0943+10, P_3 results from drifting subpulses. Under the CM, the subbeam carousel rotates about the magnetic axis, causing subbeams to appear at different longitudes for different pulses. This effect causes the observed subpulse drifting.

 P_3 is therefore a measure of the time between adjacent subbeams crossing the same longitude in the profile. Two variations can then account for a change in P_3 : a change in the angular separation between subbeams (as measured in the plane perpendicular to the magnetic axis) or a change in the angular velocity of the carousel (hereafter: ω_c with a corresponding change in \hat{P}_3 . In either case, small changes in the viewing geometry will not affect P_3 .

It is not simple to resolve which of these effects causes the observed change in P_3 , but to understand the physics of moding and pulsar emission we must answer this question. We consider what observational evidence we have concerning this matter.

1. Change in carousel angular velocity ω_c

If ω_c decreases, then the subbeams will cross a given longitude on the polar cap less frequently, thus changing the observed P_3 . Similarly, the rate of change of the position on the polar cap of a given subbeam will decrease. This will cause the subbeam to appear to drift less quickly across the pulse window.

The drift rate of B0943+10 is fast enough that an individual subpulse cannot often be observed in consecutive pulses: after being observed in one pulse, the subpulse has left the pulse window by the next pulse. To observe the track of a subpulse across the pulse window, we follow the method used in $Paper\ I$. An LRF is performed on a 256-pulse segment of the pulse sequence from which the frequency of the primary modulation feature is determined. The 256 pulses are then folded according to the phase position within $P_{3,obs}$. This results in a single sequence of length $P_{3,obs}$ from which we can resolve the rate at which a subbeam crosses the pulse window. To mitigate wrapping effects, the resulting sequence is plotted twice. This process shall be referred to as a modfold. Fig. 4 shows the results of a modfold.

If ω_c alone determines the variation in P_3 , \hat{P}_3 must change by some 5%, and there will be a corresponding

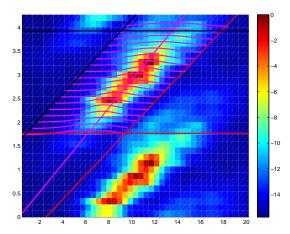

Figure 4. Sample results of a modfold: the track of a subpulse across the pulse window for the MJD 53491 AO observation, performed over pulses 1-256. Longitude in deg. is plotted on the horizontal axis and time in units of P_1 is plotted on the vertical axis. A 256-pulse LRF was performed to determine $P_{3,obs}$. The same pulse sequence was folded at $P_{3,obs}$ and plotted twice. A bounding box (red and black) was drawn around the subpulse track. Gaussians (magenta) were fitted to each row in the bounding box and a line (magenta) was then fitted to the peaks of the Gaussians, from which m (see eq. 4) was determined.

change in the slope of the subpulse traverse (see Fig. 4). Under the CM, we expect the traverse of a subbeam to deviate from a line due to our curved sightline (as projected on the polar cap) and the curvature of the carousel. In the case of B0943+10, our sightline traverse is tangential: essentially cutting the edge of the cone, so across the $\sim\!20^\circ$ pulse window we expect any deviation from linearity to be minimal, as observed.

We may therefore treat the subpulse traverse as linear. Since we are concerned only with changes in the subpulse traverse, and since the shape of the traverse is determined by our viewing geometetry which is assumed to be constant, the linear approximation is further justified. As such, the slope (m) is then determined by $P_{3,obs}$ and the spacing between adjacent subpulses in the pulse window (P_2) :

$$m = \frac{P_{3,obs}}{P_2} \tag{4}$$

For a constant P_2 , a 5% change in $P_{3,obs}$ will produce a 5% change in m.

Fig. 4 demonstrates the determination of m for one 256-pulse subsequence. A modfold is performed. A bounding box is drawn around the track of a subpulse. The subpulses are quite Gaussian in form, so a Gaussian is fitted to each row of intensities within the bounding box. We then have a stack of Gaussians whose peaks align with the centers of the subpulses. The peak positions of the Gaussians are fitted to a line, and the slope of this line is taken to be m. The slopes so determined are fairly stable with respect to changes in the bounding box.

A 5% change in m is very small given the accuracy of the method described above. The GMRT observation is not of sufficiently high quality to resolve m clearly, so the older AO observations were used to determine m as a function of

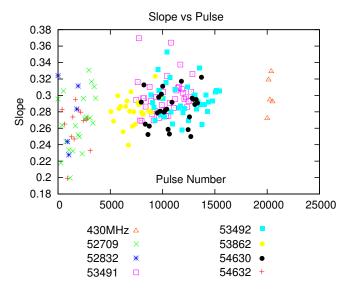

Figure 5. Drift-band slope in periods/°longitude as a function of time since 'B'-mode onset for eight AO observations—as in Fig. 4. The position within each 'B'-mode observation was determined by measuring $f_{3,obs}$ and fitting to eq.(1). There appears to be a gradual increase in the slope (m) of about 5%.

time. For the observations used below (see *Papers I, IV and V*), m was determined for the first 256-pulse subsequence in the 'B' mode, then it was determined for a 256-pulse subsequence beginning 128 pulses later. Then the process was reiterated until the end of the mode (or observation).

Fig. 5 shows m as a function of time. The m values exhibit a great deal of scatter compared to the expected 5% change we are trying to detect. Errors in the measurement of m would be expected to be of comparable magnitude: the extension of the subpulses is large compared to the total drift, their shapes deviate significantly from a Gaussian, the signal-to-noise ratio even after folding 256 pulses is still low enough to affect the fits, and the changing P_3 at the beginning of the 'B' mode smears the apparent subpulse track.

 $P_{3,obs}$ decreases by about 5% during the course of a 'B' mode. If changes in ω_c were solely responsible for the changes in $P_{3,obs}$, then P_2 would remain constant, and m would vary proportionally to $P_{3,obs}$. However, a 5% decrease in m is not observed—in fact, m appears to increase by about 5% (Fig. 5). Thus, a carousel velocity change alone cannot account for the observations.

2. Change in subbeam spacing

We now explore the question of possible subbeam-spacing changes within the carousel. If the number of subbeams N is constant, then any such P_2 changes will occur on timescales small with respect to \hat{P}_3 . Such changes would correspondingly affect P_3 , but if m (eq.4) and ω_c remain constant, then P_3 will remain constant on average. $\hat{P}_3 \approx 37P_1$, so in a given 256-pulse subsequence the carousel completes about 7 rotations. Thus P_3 determined by an LRF performed over the subsequence will not be significantly affected.

A change in P_3 must therefore be attributed to a change in the number of subbeams: this will affect the average angular spacing of the subbeams. According to the current

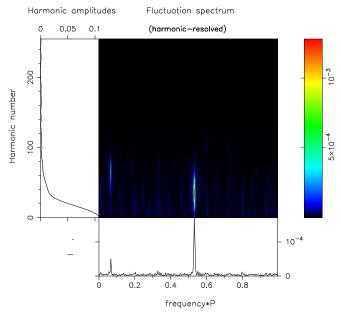

Figure 6. Harmonically-Resolved Fluctuation spectrum (HRF) performed on the first 256 pulses of the MJD 53492 AO observation. The frequency spectrum folded at f_3 is plotted in the bottom panel, excluding the bins corresponding to the pulsar frequency and its harmonics. The intensity of the pulsar harmonics as a function of harmonic number is plotted in the left panel. The center panel shows the intensity of the features lying at $(N+f)/P_1$ as a function of pulsar harmonic number N and frequency f where $0 < f < \frac{1}{P_1}$.

model of B0943+10, the number of subbeams is ~ 20 (Pa-per~I). The smallest change in the average subbeam spacing must therefore be 5%, and in turn P_3 will change by 5%. This conflicts what is observed: the primary modulation frequency appears to change smoothly by 5% over the course of a 'B'-mode apparition (see Fig. 3)—not in discrete jumps.

However, if the number of subbeams changes on timescales less than 256 pulses, smooth changes in the observed P_3 could be explained. If the carousel has multiple configurations each with a different number of sparks, then the fraction of time it spends in each configuration will determine the observed P_3 . Gradual changes in the fractional time spent in each configuration would then cause gradual changes in P_3 .

In order to distinguish variations in the subbeam spacing we can determine P_2 . As with the determination of m, a P_2 change of around 5% could explain the observed P_3 variations, but achieving such precision is difficult. As discussed in $Paper\ I,\ P_2$ is around 10° of longitude. This is large with respect to the profile width, so it is difficult to observe single pulses with two subpulses: few pulses exhibit more than one and, in the few that do so, they fall on the profile wings where they are characteristically faint. Thus, we cannot measure P_2 directly.

We therefore follow the analysis presented in *Paper I*. A Fourier transform was performed on an unfolded time series. The frequency of the pulsar and its harmonics are strongly visible in the frequency domain. Additionally, components due to P_3 falling at $(N + f_3)/P_1$ are visible, where N is the

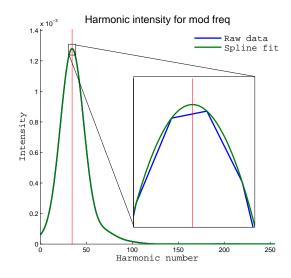

Figure 7. A plot of modulation intensity vs. harmonic number for primary modulation feature, using the HRF computed in Fig. 6.

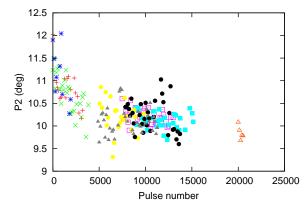

Figure 8. P_2 as a function of time in the 'B' mode for nine AO observations. P_2 was measured by performing an HRF as in Fig. 6. Using the frequency bin corresponding to the primary fluctuation feature, the peak of the features lying at $(N+f_3)/P_1$ was found, from which $P_2 = 360^{\circ}/N_{max}$.

harmonic number of the pulsar rotation frequency. The amplitudes of these components peak around $N_{max} \approx 35$ (see Figs 6 and 7). N_{max} then represents the harmonic of P_1 associated with the primary subpulse-modulation frequency—or, in analogy with eq.(4), $f_{3,obs} = 1/(N_{max}P_2)$. P_2 (given its units in degrees) can then be calculated as $360^{\circ}/N_{max}$, where N_{max} is the harmonic number corresponding to the peak amplitude.

To determine f_3 , the fluctuation spectrum is folded at the pulsar frequency. Fig. 6 shows an harmonically resolved fluction spectrum (HRF). The folded frequency domain is plotted in the bottom panel with the pulsar harmonics (now the DC component) removed. The left panel shows the amplitude of the pulsar harmonics as a function of harmonic number. The center panel shows the amplitude of the components of the folded Fourier transform as a function of the pulsar harmonic number.

The primary modulation peak in the folded Fourier do-

main determines f_3 . Fig. 7 shows the amplitudes of the $(N + f_3)/P_1$ components for the HRF plotted in Fig. 6. A cubic spline fit was performed to find the position of the peak. Generally, the amplitudes change smoothly, so that the splines fit the amplitudes well. There is typically a clear maximum.

In this manner, P_2 was determined as a function of position in 'B' mode for the available AO observations. The position of each AO observation in 'B' mode was found by exploiting the changes in $f_{3,obs}$. For each observation, $f_{3,obs}$ was found as a function of time by performing 256-pulse LRFs. The results were then fitted to eq.(1) and are plotted in Fig. 8. P_2 appears to decrease in a manner similar to the increase in P_3 , changing by about 10% over the course of the 'B' mode.

The average pulse profile changes shape with the same time scale as the changes in P_3 and with a manner very similar to the observed changes in P_2 . We were concerned that the changing profile shape or the changing P_3 could affect our measurement of P_2 , thereby producing the illusion of a change in P_2 . To resolve this question, a modeled pulse sequences was produced to test our method of finding P_2 (see Fig. 9).

The subpulses were modeled as a positively valued sine wave $(i.e., 1+sin\phi)$. The period of the sine wave was set to be 10° longitude corresponding to the observed P_2 . The pulses were modeled by multiplying the sine wave by a 'B' mode average profile taken from an AO observation with the off-pulse window set to 0. The phase of the subpulse sine wave was increased by $2\pi P_1/P_3$ from pulse to pulse to simulate subpulse drifting.

To check if changes in the average profile affect measurements of P_2 two methods were followed. First, 256-pulse average profiles were calculated from an AO observation beginning at 'B' mode onset. The pulse window over which the profile was calculated was incremented by one pulse and the process was completed for the remainder of the 'B' mode. In order to mimic the pulse shape changes, the pulses were modeled using these average profiles according to the method above. For the second method, a 256-pulse profile was calculated for the beginning and the end of a 'B' mode. An exponential function was used to interpolate the changes in each bin of the profile for the several thousand pulses in the 'B' mode, thus producing a smoothly changing average profile to be used to model pulses.

The modeled pulse sequence was then analyzed in the same way as the observations to determine P_2 . No change in P_2 greater than a fraction of a percent was observed using the modeled data, from which we conclude that the gradual changes in profile shape cannot account for the observed change in P_2 .

To see if the change in P_3 affects measurements of P_2 we used both a constant and a changing 'B'-mode average profile while altering P_3 as a function of pulse number according to eq.(1) given the relation in eq.(2). No change was detected in the measurement of P_2 in the modeled sequence, from which we conclude that the changing P_3 cannot account for the observed changes in P_2 .

Thus, we observe a decrease in P_2 by about 10% during the 'B' mode. This change appears to be fairly continuous.

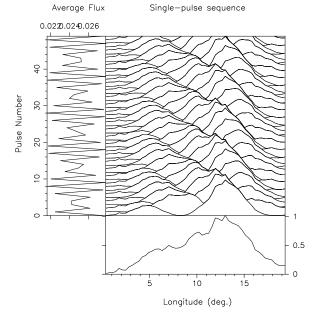

Figure 9. A simulated pulse sequence for B0943+10. A 50-pulse stack is plotted in the center panel. The average of those 50 pulses is plotted in the bottom panel, and the flux for each pulse is plotted in the left panel. Subpulses were modeled by a positively valued sine wave. Pulses were modeled by multiplying the subbeam sine wave by an average profile which changed from pulse to pulse. For each pulse, the subpulse phase was increased by $2\pi P_1/P_3$ to simulate subpulse drifting.

 $P_{3,obs}$ decreases by about 5% over a similar timescale.² By eq.(4) we would expect these two effects to produce a \sim 5% increase in the slope of the subpulse track, which agrees with the measurements of m (Fig. 5). We conclude that there is an intrinsic change in the slope of the subpulse track.

Under the CM, this change in the slope indicates a change in ω_c . Accounting for aliasing, the observed decrease in $P_{3,obs}$ corresponds to an increase in the true P_3 . From eqs.1 and 2 we see there is an increase in P_3 of 4.1% during the 'B'-mode. Due to our tangential sight-line traverse, P_2 should be inversely proportional to the number of subbeams N. According to the CM, $\hat{P}_3 = 2\pi/\omega_c = NP_3$. Thus we can say:

$$P_2 \propto \frac{1}{N} \tag{5}$$

$$P_3 \propto \frac{1}{\omega_c N}$$
 (6)

Combining these two equations tells us:

$$\omega_c \propto \frac{P_2}{P_3} \tag{7}$$

Given a 10% decrease in P_2 and a 4.1% increase in P_3 during the 'B'-mode, eq.(7) tells us there should be a 13.5% decrease in ω_c . Since $\hat{P}_3 \propto 1/\omega_c$, there is a 16% increase in \hat{P}_3 during the 'B'-mode.

 $^{^2}$ P_3 variations can in principle "Doppler shift" P_2 ; e.g., see Gupta et al. (2004), eq. (5). However, for B0943+10 here these effects are at the 1% level.

V. DISCUSSION

We have presented a long, 8-hr observation of B0943+10 using the GMRT telescope in India. Such a long observation of the pulsar is important for resolving questions about the behavior of the long modes in B0943+10. We confirm the gradual evolution of the primary fluctuation feature which corresponds to subpulse drifting in the 'B' mode. From 'B' mode onset until 'B' mode cessation, $f_{3,obs}$ varies according to eq.(1) with a characteristic time of $\tau=1.2$ hr. This supports the conclusions of earlier papers in this series that during the course of a 'B' mode there are changes in the average profile with a similar characteristic time as well as a gradual increase in the fractional linear polarization during a 'B' mode.

As a rough estimate, we find that 'B' modes will persist for around 7.5 hrs in length and 'Q' modes some 2.2 hrs. Significant deviation from these numbers is expected (and is observed for the 'Q' mode).

The previous papers in this series have argued that the emission from B0943+10 can be understood according to the subbeam-carousel model, wherein 20 evenly spaced subbeams rotate around the magnetic axis in about $37\ P_1$.

We detect a decrease in P_2 of about 10% during the course of a 'B' mode. Under the carousel model, this indicates an increase in the number of subbeams. Given about 20 subbeams, there should be two more subbeams at the end of 'B' mode than at the beginning. Backus et al. (2010) found three occasions, lasting some several hundred pulses, where the number of subbeams was measurable. These three occasions spanned the entire 'B'-mode. Using the analysis presented in \S IV, P_2 is found to decrease as expected for these occasions. For all three, N was found to be 20, which seems to contradict the fact that P_2 measurements indicate an increase in N. However, in Backus et al. (2010), the measurement of N at the beginning of the 'B'-mode has a large error due to low signal-to-noise in the LRF used to compute N. Thus the findings of Backus et al. (2010) are commensurate with a carousel composed of 20 subbeams at the end of the 'B'-mode and fewer subbeams (perhaps 18) at the beginning.³

For $N \approx 20$, one would expect discrete jumps of about 1/20=5% in our measurements of P_2 . However this is not observed. Rather, the changes in P_2 appear continuous, albeit with significant scatter. Our measurements of P_2 are calculated over several hundred pulses, so if the carousel model is correct the pulsar must switch between two configurations with a different number of subbeams on timescales much less than several hundred pulses. This indicates that the pulsar preferentially spends more time in one configuration at the beginning of 'B' mode and gradually spends more time in other configurations.

By measuring P_2 , P_3 , and the slope of subbeams as they cross the pulse window—which gives a measure of how quickly a given subbeam passes through a degree of longitude—we find that over the course of a 'B' mode \hat{P}_3 increases by some 16% rather than the 5% found in *Paper I*.

We may now speculate on a possible physical explanation of the gradual changes in \hat{P}_3 . According to the partially screened gap model (PSG), the $\mathbf{E} \times \mathbf{B}$ drift velocity of the subbeams around the magnetic axis should be related to the temperature of neutron star surface at the polar cap. In the PSG model, the vacuum gap as proposed by Ruderman & Sutherland (1975) is actually partially filled with ions (or possibly electrons). Heating of the neutron star surface due to bombardment by relativistic particles causes the ejection of charge carriers into the vacuum gap. This shields the potential drop ΔV across the vacuum by some factor $0 < \eta < 1$ such that $\Delta V = \eta \Delta V_{RS}$, where ΔV_{RS} is the potential drop across a purely vacuum gap (Gil et al. 2003).

The drift velocity, and hence ω_c , should be proportional to ΔV , thus $\hat{P}_3 \propto \eta^{-1}$ (Gil et al. 2006). We observe a 16% increase in \hat{P}_3 over a 'B'-mode apparition, so we can say:

$$\frac{\hat{P}_{3,2}}{\hat{P}_{3,1}} = \frac{\eta_1}{\eta_2} = 1.16 \tag{8}$$

According to Gil et al. (2003):

$$\eta = 1 - \exp[C(1 - T_c/T_s)]$$
(9)

where T_s is the surface temperature of the neutron star, T_c is the critical temperature at which the potential drop is completely shielded (i.e. $\Delta V = 0$) and C is a constant. As argued by Gil et al. (2003), T_s should be at most a few percent less than T_c , so the argument of the exponent in eq.(9) is close to 0. Performing a Taylor expansion and keeping the terms up to first order:

$$\eta \approx -C(1 - T_c/T_s) \tag{10}$$

From eq.(8) and eq.(10) we find that the ratio of the surface temperature at the end of a 'B'-mode to the temperature at the beginning should be:

$$\frac{T_{s,2}}{T_{s,1}} \approx \frac{1.16T_c}{T_c + 0.16T_{s,1}} \tag{11}$$

Now, $T_s \lesssim T_c$. So for $0.9T_c < T_s < T_c$ we find that $1 < T_{s,2}/T_{s,1} < 1.014$. This means that according to the PSG model we should expect to see an increase in the surface temperature of less than 1.4% over the course of a 'B'-mode. B0943+10 has been observed in the X-ray regime (Zhang et al. 2005), and it may be possible with long simultaneous X-ray and radio observations to detect such small changes in the temperature. This would be strong evidence in favor of the PSG model, along with the carousel model.

Acknowledgments: We are pleased to acknowledge Svetlana Suleymanova and Geoffrey Wright for their critical readings of the manuscript. We thank the GMRT staff for support during the observation. Two of us (IB and JMR) thank the National Centre for Radio Astrophysics in Pune for their generous hospitality. Portions of this work were carried out with support from US National Science Foundation Grants AST 99-87654 and 08-07691. Arecibo Observatory is operated by Cornell University under contract to the US NSF. This work used the NASA ADS system.

 $^{^3\,}$ See Backus et al. (2010) figures 1, 2, and 3 for the measurements of N.

⁴ We should perhaps not forget here that the pulsar's varying 'B'-mode profile forms exhibit a different type of "screening" such that 'beamlets' are visible across the entire emission window at 'B'-mode onset but only in the leading part of the window after an hour or so. Whether these two types of "screening" are somehow physically related is currently not clear.
