

## Intra-class correlation coefficients

There's six different formulas for calculating the ICC which depend on the purpose of the study, the design of the study and type of measurements taken. The first number designates the *model*, and the second number designates the *form*.

### "Models" of the ICC

Model 1 – each subject is assessed by a *different set of randomly selected* raters. This is rare in reliability studies.

Model 2 – each subject is assessed by each rater, and raters have been *randomly selected*.

Model 3 – each subject is assessed by each rater, but the raters are the only raters of interest.

### "Form" of the ICC

The form reflects whether the reliability is to be calculated on a single measurement or by taking the average of 2 or more measurements taken by different raters. In most cases, the form will be 1, however if you want to test whether taking an average of 3 raters' scores improves reliability, you might use form 2,3,4,etc.

Single measurement = 1

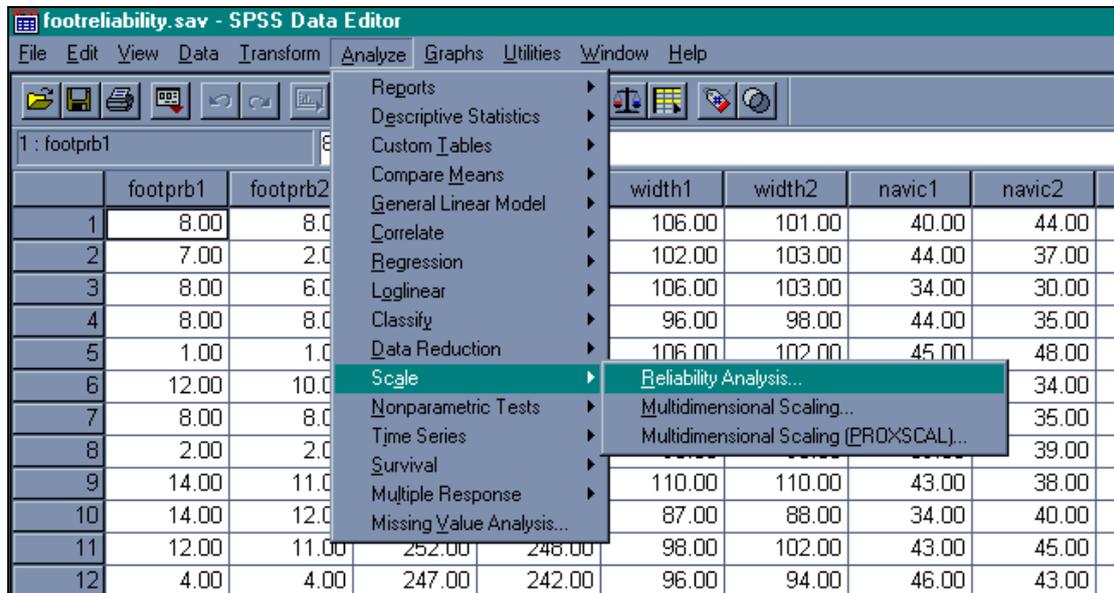

Average of 2 measurements = 2

Average of 3 measurements =3....etc

ICC type	Description
ICC(1,1)	Each subject is assessed by a <i>different set of randomly selected</i> raters, and the reliability is calculated from a single measurement. Uncommonly used in clinical reliability studies.
ICC(1,k)	As above, but reliability is calculated by taking an average of the <i>k</i> raters' measurements.
ICC(2,1)	Each subject is measured by each rater, and raters are considered representative of a larger population of similar raters. Reliability calculated from a single measurement.
ICC(2,k)	As above, but reliability is calculated by taking an average of the <i>k</i> raters' measurements.
ICC(3,1)	Each subject is assessed by each rater, but the raters are the only raters of interest. Reliability calculated from a single measurement.
ICC(3,k)	As above, but reliability is calculated by taking an average of the <i>k</i> raters' measurements.

## How to do ICCs in SPSS

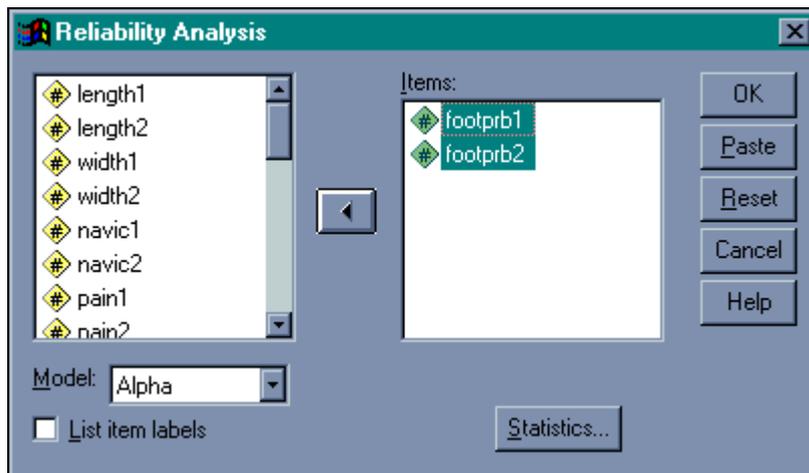

1. Select Analyze/Scale/Reliability analysis:

The screenshot shows the SPSS Data Editor window for a file named 'footreliability.sav'. The 'Analyze' menu is open, and the 'Scale' option is selected, which has opened a sub-menu where 'Reliability Analysis...' is highlighted. The data table below shows the variables and their values for 12 cases.

	footprb1	footprb2	width1	width2	navic1	navic2		
1	8.00	8.00	106.00	101.00	40.00	44.00		
2	7.00	2.00	102.00	103.00	44.00	37.00		
3	8.00	6.00	106.00	103.00	34.00	30.00		
4	8.00	8.00	96.00	98.00	44.00	35.00		
5	1.00	1.00	106.00	102.00	45.00	48.00		
6	12.00	10.00				34.00		
7	8.00	8.00				35.00		
8	2.00	2.00				39.00		
9	14.00	11.00	110.00	110.00	43.00	38.00		
10	14.00	12.00	87.00	88.00	34.00	40.00		
11	12.00	11.00	252.00	248.00	98.00	102.00	43.00	45.00
12	4.00	4.00	247.00	242.00	96.00	94.00	46.00	43.00

2. Select your two columns of data and click on Statistics:

The screenshot shows the 'Reliability Analysis' dialog box. The 'Items' list on the left contains 'length1', 'length2', 'width1', 'width2', 'navic1', 'navic2', 'pain1', and 'pain2'. The 'Items' list on the right contains 'footprb1' and 'footprb2'. The 'Model' is set to 'Alpha'. The 'List item labels' checkbox is unchecked. The 'Statistics...' button is visible at the bottom.

3. Click the intraclass correlation coefficient checkbox.

4. You have two options to choose from here:

*Model:* Two-way mixed OR Two-way random OR one-way random

*Type:* Consistency OR Agreement

This is because SPSS doesn't stick to the standard ICC nomenclature. Here's how to define the ICC models:

ICC model	What SPSS calls it
Model 1	One-way random
Model 2	Two-way random
Model 3	Two-way mixed

The *type* gives you the option of working out whether the error involved in the measurement is systematic or not (ie: are the measurements "offset" between trials or between raters. If this is considered important, you select "Absolute agreement", otherwise leave the default as "Consistency". If you are also using paired t-tests to check for systematic differences between trials, you needn't worry about selecting "Absolute agreement" as you will have already worked out if there are systematic differences.

5. The output is a typically ugly SPSS number that looks like this:

```

→ Reliability

***** Method 1 (space saver) will be used for this analysis *****
□

      R E L I A B I L I T Y   A N A L Y S I S   -   S C A L E   ( A L P H A )

                                Intraclass Correlation Coefficient

Two-Way Mixed Effect Model (Consistency Definition):
People Effect Random, Measure Effect Fixed
Single Measure Intraclass Correlation =      .9170*
  95.00% C.I.:                Lower =      .8353      Upper =      .9591
F = 23.1064  DF = (    30,    30.0)  Sig. = .0000 (Test Value = .0000 )
Average Measure Intraclass Correlation =      .9567**
  95.00% C.I.:                Lower =      .9102      Upper =      .9791
F = 23.1064  DF = (    30,    30.0)  Sig. = .0000 (Test Value = .0000 )
*: Notice that the same estimator is used whether the interaction effect
  is present or not.
**: This estimate is computed if the interaction effect is absent,
  otherwise ICC is not estimable.

```

Two lots of ICC data are produced: one for the single measure, and one for the average measure. You decide which one to document based on the “form” of the ICC (ie: whether you take a single measure or whether you average the measurements from multiple raters). Though it may be tempting to document the average measure (as it will be a better ICC), this is cheating unless you have decided *a priori* to use an average. In most cases, you will be using a single measure anyway.

## Summary

ICC type	What SPSS calls it
ICC(1,1)	One-way random, single measure
ICC(1,k)	One-way random, average measure
ICC(2,1)	Two-way random, single measure
ICC(2,k)	Two-way random, average measure
ICC(3,1)	Two-way mixed, single measure
ICC(3,k)	Two-way mixed, average measure
